
Arrow: the invader fixates in the resident population with probability above neutral drift $1/Z=0.01$, drawn from the displaced population toward the strategy that displaces it, in the invader's colour. Disc area: share of the independently simulated finite-mutation chain ($\beta=2$, $\mu=0.02$), because the small-mutation transition has more than one absorbing class here and its stationary vector is not unique. No language-model route plays this process.
